Breast Neoplasms; Ampulla of Vater; Jaundice; Obstructive/etiology; Neoplasm Metastasis

Abstract
Breast cancer is the most common tumor in women and the first cause of death for malignancy in the female. Bile ducts are not among the common sites of metastasis from breast cancer. Few cases of obstructive jaundice due to metastatic breast cancer have been described in the literature and they mostly resulted from widespread liver metastases that eventually involved the bile ducts. We report an exceptional case of ampullary metastasis in the absence of liver metastases.

Sporadic reports have been published about the involvement of the ampulla by breast cancer metastasis. This case emphasizes the need to consider this diagnosis in women presenting with obstructive jaundice, especially when there is a clinical possibility of breast cancer.

Metástase Ampular de Neoplasia da Mama: Uma Causa Rara de Ictericia Obstrutiva

Resumen
El cáncer de mama es el tumor más común en mujeres y la primera causa de muerte por neoplasia en esta población. Las vías biliares no son sitios comunes de metastatización de cáncer de mama. Pocos casos de ictericia obstructiva debido a metástasis mamarias han sido descritos en la literatura y ocurren principalmente debido a metástasis hepáticas que comprimen a la vía biliar. Relatamos un caso excepcional de metástasis ampular en ausencia de metástasis hepáticas.

1. Introduction

Breast cancer is the most common malignancy in women, with over a million newly diagnosed cases each year and being one of the leading causes of cancer death among them.\textsuperscript{1—3}

In 10\% of the cases distant metastases are already present at the time of the diagnosis.\textsuperscript{4—6} Breast cancer metastases occur through contiguous, lymphatic and hematogenous spread. Common sites of metastasis include bone, lung, lymph nodes, liver and brain. Virtually every site of the human body can be targeted by hematogenous spread of breast cancer. However, metastases to the digestive tract, the kidneys and retroperitoneal organs have only been occasionally reported.\textsuperscript{4—6} Gastrointestinal tract involvement is detected in only 10\% of all the cases.\textsuperscript{4—6} Widespread liver metastases that compress or infiltrate the biliary ducts can sometimes cause obstructive jaundice, whilst a direct metastatic involvement of the extrahepatic bile ducts in absence of hepatic lesions is exceptional.\textsuperscript{4—6}

We report a singular case of obstructive jaundice due to a metastatic breast cancer to the ampulla of Vater. To the best of our knowledge and review of the literature there have been only few similar reports.\textsuperscript{7—10}

This case emphasize that diagnosis can be difficult and controversial when metastasis from breast cancer occurs at uncommon sites, but quick and accurate diagnosis is needed for an adequate treatment choice.

2. Case presentation

A 59-year-old female was admitted to the emergency department with mucocutaneous jaundice associated with pruritus. No dark urine, acholic stools, abdominal pain, fever, anorexia or weight loss were present. Personal history included systemic lupus erythematosus (treated with hydroxychloroquine sulfate and mycophenolate mofetil), type 2 diabetes mellitus non-insulin treated and a breast lump (detected about a month ago in breast cancer screening mammography) under investigation (histology ongoing). The laboratory tests showed an obstructive pattern with total bilirubin 9 mg/dL, direct bilirubin 6.4 mg/dL, aspartate aminotransferase 126 IU/L, alanine aminotransferase 208 IU/L, gamma glutamyl transpeptidase 796 IU/L, alkaline phosphatase 726 IU/L and negative inflammatory parameters. Blood tumor markers (cancer antigen 19.9 and carcinoembryonic antigen) were within normal ranges. The abdominal ultrasound study was limited by bowel gas interposition but allowed view marked dilatation of intrahepatic bile ducts and common bile duct 14 mm and could not define the cause of obstruction. Abdominal tomography confirmed dilatation of hepatic bile ducts (common bile duct with 15 mm without evidence of choledocholithiasis) and showed an ampullary mass with 13 mm of diameter suggestive of ampullary adenoma without suspicious abdominal lymph nodes (Fig. 1). Endoscopic retrograde cholangiopancreatography (ERCP) showed papilla of Vater with moderately increased volume and irregular mucosal suggestive of congestive ampullary adenoma. Biopsies were performed and two plastic biliary stents were placed. Histology showed infiltration by invasive ductal carcinoma of the breast (Fig. 2). During hospitalization the histology of the breast nodule revealed an invasive breast carcinoma and the patient initiated chemotherapy (including trastuzumab). Further evaluation with chest tomography and radionuclide bone scanning revealed the presence of bone metastases. For better palliation, three months after the plastic stent implantation, patient underwent repeat ERCP with the placement of a metal stent due to its better efficiency. At discharge and several weeks later the repeated laboratory tests revealed regression of cholestasis. The patient succumbed to metastatic disease 1 year later of the diagnostic without jaundice or abnormal liver function tests.

Figure 1 Computed tomography showed an ampullary mass with 13 mm suggestive of ampullary adenoma.
3. Discussion

Breast cancer is the most commonly diagnosed cancer worldwide, with more than 1,384,000 cases detected each year. It is the main cause of death from cancer in females and the second in the general population, after lung cancer.1-3

Distant metastases of breast carcinoma are present in about 10% of patients at the time of diagnosis, while 30% of patients will develop metastatic disease following surgery and/or chemotherapy, radiotherapy or endocrine therapy.3

The most common sites of breast cancer metastases are the bone, lung, liver and brain, while the involvement of gastrointestinal tract is rare and can pose a diagnostic challenge.1-3 Metastatic breast cancer can cause obstructive jaundice when multiple liver lesions are present, the bile duct is compressed by enlarged lymph nodes or, more rarely, when the head of the pancreas is involved.4-6 The biliary tract is very rarely affected by metastases in general, and in these cases, colorectal cancer is the most frequent malignancy involved. Other reported primary tumors causing metastatic biliary obstruction include malignant melanoma, lymphoma, gallbladder, stomach, esophagus, liver, ovary, cervix, uterus, muscle, kidney, prostate, bone and brain. Isolated breast cancer metastasis to the biliary tract, gallbladder and Vater ampulla are exceptional.6,49 It is important to recognize this group of patients because in patients with normal liver function, relief of biliary obstruction using surgical bypass or biliary stenting extends their survival to over 1 year, in comparison to those with liver metastases, whose mean survival is only about 1 month.11-13

By reviewing the literature there were only a few cases of extrahepatic biliary tract metastasis from breast cancer involving the peripancreatic area.5-10 A common feature of all the reports available in the literature is that the diagnosis was not achieved nor suspected before endoscopy biopsy and/or surgery. Similarly, in the majority of the cases there was a long interval between the diagnosis of the primary tumor and the development of metastases affecting the biliary tract. This timing can make it hard to suspect a relationship between the breast cancer and the biliary disease.7-10 In our case this was the first evidence of metastatic breast cancer. Patients with a history of malignancy found to have obstructive jaundice from an ampullary mass should undergo further investigation to determine primary biliary cancer versus metastatic disease in order to provide appropriate surgical and medical management. Nowadays, numerous modalities such as extracorporeal ultrasonography (US), esophagogastroduodenoscopy, biopsy, computed tomography (TC), magnetic resonance (MRI), endoscopic ultrasonography (EUS), ERCP, intraductal US and angiography are available for diagnosing ampullary neoplasms. Appropriate and efficient selection of such modalities is necessary for lessening procedure-related complications as well as the burden on the patients.14 It is not always possible to distinguish adenoma from carcinoma or metastatic involvement of the ampulla with duodenoscopy only, and histological evaluation by forceps biopsy is mandatory for establishment of a definitive diagnosis. The diagnostic accuracy of forceps biopsy in ampullary neoplasms reportedly ranges from 47 to 95%.14 Immunohistochemistry plays a key role for indicating the histological type of the tumor, since the metastases of breast carcinoma to the gastrointestinal tract have an endoscopic, radiological and histological aspect similar to the adenocarcinoma poorly differentiated with signet ring cells.10 Tumor staining with EUS and/or intraductal US can provide useful information for making therapeutic decisions, especially in the selection of patients for endoscopic papillotomy.14 CT/MRI is recommended for the detection of distant metastases. EUS can be performed in a single session with ERCP, biopsy and biliary stent placement (if indicated).14

Patients with metastatic breast cancer in the biliary tract need a long-term palliative treatment strategy. The use of novel chemotherapy, hormonal therapy and irradiation in conjunction with biliary decompression or surgical intervention may lead to even more prolonged survival and improve quality of life.15,16 A variety of chemotherapy strategies are available for metastatic breast cancer and should be tailored for each patient along with endocrine therapy in tumors positive for estrogen and progesterone receptors.16-18 HER2 receptor-positive metastatic disease should be treated with trastuzumab in addition to chemotherapy.19

Biliary stenting is a commonly used procedure in treating patients with pancreaticobiliary malignancies, metastatic disease and external biliary compression by lymph nodes. It is used both as a bridge to surgery in patients with resectable disease and for palliation in those with biliary obstruction caused by inoperable disease.20,21 For palliation, endoscopic biliary drainage is effective in more than 80% of cases.21-25 Multiple trials have demonstrated that placement of self-expanding metallic stents in patients with malignant obstruction of the common bile duct offers higher technical and clinical success rates as well as lower complication rates and a superior cumulative stent patency when compared with plastic stent placement.21-25 Initial insertion of a plastic stent is most cost-effective if patient life expectancy is shorter than 4 months, if it is longer than 4 months then initial insertion of a self-expanding metallic stents is more cost-effective.21-25 In our case, we first placed a plastic stent to gain symptomatic relief, but after knowing the result of
histology, we replaced it with a metal one 3 months after the first intervention.

The present report provides evidence that metastases from breast cancer can target the extrahepatic bile ducts in the absence of liver involvement, and the invasion of the bile duct wall can also be the first sign of advanced disease, thus making the diagnosis particularly difficult. Although gastrointestinal involvement in breast cancer is rare, in patients with a history of a breast lump, the possibility of biliary localization of metastatic disease should be always considered in the differential diagnosis of obstructive jaundice whose origin is unclear, especially because this condition is amenable to palliation and improve survival rate.
