ABSTRACT

Maternal folic acid (FA) supplementation is one of the most popular nutritional interventions during pregnancy for its protective effect against neural tube defects (NTDs).

The purposes of this review are: (a) to gather the current evidence regarding supplementation of maternal diet with FA and (b) to problematize the available literature in terms of dosages, critical temporal windows, and its potential benefits and risks.

The expression (pregnancy OR fetus OR offsporn OR mother) AND (“folic acid” AND supplementation) was searched on PubMed database, filtering for articles published from 2005 to 2014. Publications referring to FA supplementation during the periconceptional period or pregnancy in which there was a conclusion about the effects of isolated FA supplementation on pregnant woman, pregnancy or offspring were included. Of the initial 1182 papers, 109 fulfilled the inclusion criteria.

The majority of the publications reported FA supplementation outcomes on offspring’s health, with emphasis in NTDs, allergy/respiratory problems, cancer and behaviour problems. Some inconsistency is observed on the impact of FA supplementation on different outcomes, except for NTDs. It is also visible an increased concern about the impact of excessive supplementation, either in terms of doses or exposure’s duration.

In conclusion, there is a growing interest in FA supplementation issues. The protective effect of FA supplementation over NTDs has been confirmed, being the periconceptional period a critical window, and it is frequently suggested that allergy/respiratory outcomes arise from (excessive) FA supplementation particularly later in pregnancy. Further research on critical doses and time of exposure should be conducted.

Introduction

Folate is a term that refers to a group of water-soluble vitamins of the complex B which are naturally found in foods such as leafy green vegetables, citrus fruits and liver. Folic acid (FA), the synthetic and completely oxidized form of folate, is used in vitamin supplements and in fortified cereal products.

Within the cells, folates act as cofactors in reactions which are determinant in cell division and cell maintenance, as well as in the regulation of gene expression through epigenetic mechanisms.\textsuperscript{1} Indeed folates are a source of s-adenosylmethionine, the main cellular methyl donor that modulates genome-wide methylation thus regulating the expression of genes. This is believed to be the process by which folates affect foetal programming. In addition, folates have a determinant role in the re-methylation of plasma homocysteine to methionine,\textsuperscript{2} for which blood folate levels correlate negatively with blood homocysteine levels.

Maternal FA supplementation is one of the most popular nutritional interventions during pregnancy and it has been extensively studied for its effect on neural tube formation and foetal growth\textsuperscript{3} as folate deficiency at conception and during pregnancy may lead to abnormal development.\textsuperscript{4}

Particularly since the 1990s, when evidence emerged about the protective effect of FA supplementation against the recurrence and occurrence of neural tube defects (NTDs),\(^5\)\(^6\) there has been increasing concern about the role of periconceptional dietary supplementation and fortification strategies, as NTDs represents an important cause of morbidity and mortality.\(^7\)

Many countries worldwide practice mandatory fortification of cereal grain products with FA, as a public health policy, and several EU countries maintain a voluntary fortification of different foodstuffs.\(^8\) In addition, the WHO preonizes the supplementation with FA, in the periconceptional period and pregnancy, with 0.4 mg FA/day (together with 30–60 mg iron), increasing up to 5 mg/day for women at high risk of birth defects.\(^9\) Notwithstanding, the WHO also pointed out that the protection against NTDs only happens when the supplementation occurs until the fourth gestational week, while supplementation in other time periods is likely to be beneficial in relation to other issues of maternal and foetal health, such as foetal growth and preterm birth. However, the evidence regarding these other outcomes is not consistent.

It is known that at 0.4 mg/day, all the oxidized form of FA is converted into biologically active metabolites during absorption, and so, its consumption is generally considered safe. Intakes above the recommended levels are likely to lead to the appearance of unmetabolized FA in foetal and maternal circulation, which has been demonstrated in countries with food fortification.\(^10\) Although the impact of this is not completely understood, it is suggested that unmetabolized FA in maternal and foetal blood may act as methyl donor for the regulation of gene expression, with consequences in foetal programming.\(^11\)

In Portugal, although the recommendations follow the WHO guidelines,\(^12\) and there are multivitamin-mineral supplements containing 0.4 mg FA or similar (which are sold without a medical prescription), the available reimbursed pills containing isolated FA have a total dose of 5 mg. This dose corresponds to approximately 12.5 times the WHO recommended dose for low risk pregnancy. Furthermore, the lack of systematized health practices in many countries, being Portugal part of the problem, may lead to excessive FA supplementation resulting from the simultaneous use of FA pills and the consumption of FA-enriched foods or FA
containing multivitamin-mineral supplements, sometimes, throughout all pregnancy. In addition, there is also a big portion of non-planned pregnancies all over the world and several studies suggest that the compliance of women to periconceptional FA supplementation varies widely.

Both folate restriction and excessive supplementation lead to epigenetic marks, raising a potential concern about its role in inducing unforeseen changes in the methylosa and thus in the phenotype of the mother and the offspring at a short or a long-term. Accordingly, a remarkable number of studies have reported the outcomes of maternal FA supplementation on the offspring’s health, addressing interactions such as in children’s asthma, cancer, insulin resistance, autism and behaviour/inattention problems.

All these facts contribute to a renewed interest in the implications of maternal nutrition, before and during pregnancy, and its influences in pre and post-natal development, raising questions related to the magnitude, timing, type and duration of exposure to FA.

This review has two main purposes: first, to gather evidence published worldwide regarding supplementation of maternal diet with FA during pregnancy and the main outcomes of this supplementation either in pregnant women or in the offspring, in a short-to-long term; second, with the pulled information, to problematize this supplementation in terms of FA dosages, critical temporal windows, as well as its potentially benefits and risks, to the mothers and offspring, regarding the current state of the art.

Methods

To conduct this systematic review, the authors searched PubMed database and included the MeSH terms “pregnancy”, “fetus”, “offspring”, “mother”, “folic acid” and “supplementation” combined in the following expression: (pregnancy OR fetus OR offspring OR mother) AND (“folic acid” AND supplementation). The search was performed in December 2014 with the following filters: all articles available published from 2005 to 2014, written in English, Portuguese, Spanish or French. The search retrieved a total of 1182 publications.

Based on our objectives, the three authors established a first list of exclusion criteria. During the process of abstract reading, some criteria were added to this first list. Abstracts were reviewed by two of the authors separately – each of them evaluated 650 abstracts, with an overlap of approximately 100 abstracts, in order to calibrate the agreement in the abstracts’ revision. The third researcher participated in the meeting where the concordance between the other two were discussed and participated in the decision of discordant classifications, as well as in the definition of new exclusion criteria throughout all the process. The agreement between both researchers was very high. Whenever doubts were raised they were shared by the three researchers and the third element was critical for the final decision.

The inclusion criteria was: all original papers referring to isolated FA supplementation during periconceptional period or pregnancy in which there was a conclusion about the effects of FA supplementation on the pregnant woman, pregnancy or offspring. Whenever the abstract was not available or if it did not clearly revealed any kind of association between the FA supplementation and the outcomes, the authors accessed the full text article to decide about inclusion or exclusion.

The exclusion criteria (and the number of excluded articles after abstract reading) were: review articles (n = 226), case reports (n = 19), letters to the editor or editorials (n = 55), clinical recommendations (n = 38), study set-up descriptions (n = 6), withdrawn studies (n = 3), duplicated studies (n = 2), studies with human cells (n = 1), studies that were not focused on the effects of isolated FA supplementation (n = 539), studies testing the capacity of FA reverting environmental, chemically or genetically-induced deleterious effects (n = 119).

So, the first abstracts’ assessment allowed the exclusion of a total of 1008 of the 1182 abstracts retrieved. At this point, the remaining 174 full-text articles were read and analyzed and this resulted in the exclusion of 65 further publications: reviews (n = 1), study set-up descriptions (n = 1), studies with human cells (n = 1), studies testing the capacity of FA reverting environmental, chemically or genetically-induced deleterious effects (n = 10), studies that were not focused on the effects of isolated FA supplementation (n = 52). Afterwards, from the initial 1182 retrieved, 1073 were excluded and 109 publications completely fulfilled the inclusion criteria of this review (see Fig. 1).

In order to systematize the findings, three tables were created containing the main features of each paper: author(s) and year of publication, country, studied population, sample size, type of study, intervention (timing and dosages of FA supplementation) and results and main conclusions. The first table describes included animal studies (Table 1), the second one, the included human studies reporting effects of FA supplementation over the offspring (Table 2) and the last one the included human studies reporting effects of FA supplementation over the mother and over pregnancy outcomes (Table 3).

Results

Of the 109 included papers, the majority of them (n = 92) were performed in humans and a total of 17 corresponded to animal studies. Considering the type of study, of the 109, most of them (n = 85, 78%) were observational in nature (whether case–control studies (n = 38), cohort studies (n = 40), or cross-sectional studies (n = 7)) and only 24 (22%) were intervention trials, a great proportion of which conducted with laboratory animals (n = 17; 70.8%).

In terms of chronology, significantly more publications were found in the last five years (n = 84; 77%) compared to the first five years of research (2005–2009).

When the papers were identified by country, there is a vast dispersion around the world. However, the most represented ones were the USA (n = 20), The Netherlands (n = 11), China (n = 11), Canada (n = 11) and UK (n = 9). The papers selected were divided in 2 main categories: animal trials and human studies. In order to further systematize the analysis, human studies were divided on those focused on health outcomes of the offspring and those on health outcomes of the mother or pregnancy. Results of each category are shown separately.

Animal trials

In the animal trials category (n = 17, Table 1), all the publications were focused on health outcomes in the offspring, and a preponderance of those related to the role of FA supplementation towards gene expression (n = 4), gene methylation (n = 2) and its consequences in embroyogenesis (n = 4) was found. Other outcomes were carcinogenesis (n = 4), including mammary tumours in the offspring (n = 2), colorectal cancer (n = 1) and medulloblastoma (n = 1); metabolic syndrome (n = 1); behavioural changes (n = 1) and seizure (n = 1).

Gene methylation and gene expression

Six of the 17 animal trials focused their attention on gene expression or methylation and globally folate supplementation during pregnancy is shown to regulate gene expression. Many of the animal studies also corroborate the impact of FA supplementation

<td>4 mg/day vs. 0 mg/day; before and during pregnancy</td>
<td>High doses of FA, when compared to none, administered to rats before and during gestation decrease their offspring seizure threshold. Maternal FA supplementation changes the expression of hepatic proteins that are involved in metabolic regulation, oxidative responses, and cancer-related processes. Supplementation with high doses of FA from the preconception through pregnancy may adversely affect embryonic mouse development. Maternal and post weaning FA supplementation significantly affects global and gene-specific DNA methylation in the rat offspring. Supplementation with high FA in an adequate B12 status does not significantly change the outcomes. Nevertheless, high maternal FA supplementation on a B12 deficient diet increases oxidative stress in both mother and pups. Chronic exposure to FA throughout generations at doses close to those achieved through fortification does not instigate or protect against chromosome damage.</td>

</table>
on gene methylation. Namely, Sie et al. demonstrated that maternal FA supplementation modulates global and gene-specific DNA methylation in the rat offspring\textsuperscript{22} and, for instance, Kulkarni et al. showed that there was a reduction in DNA methylation levels of placental tissues occurring after exposure of pregnant dams to excess of folates.\textsuperscript{23} In what concerns critical doses of supplementation, it seems that excessive supplementation (8 mg/kg instead of the recommended dose of 2 mg/kg) has a determinant role both in gene expression and gene methylation.\textsuperscript{24} However, another study concluded that chronic exposure to FA throughout generations at doses close to those achieved through fortification does not instigate or protect against chromosome damage.\textsuperscript{25}

**Embryogenesis**

Of the four trials studying embryogenesis outcomes, one suggests that high levels of FA supplementation may adversely affect foetal mouse embryonic development\textsuperscript{26} and that the excessive maternal FA supplementation on a deficient B12 diet, although not affecting neurodevelopment, may increase oxidative stress in mothers and pups.\textsuperscript{25}

In addition, folate intake during pregnancy is suggested to have a dual effect on cardiogenesis, depending on the presence of environmental toxins.\textsuperscript{27}

In all these cases, there is a common trend suggesting that high doses of FA supplementation, and also longer exposures, may indeed induce harmful outcomes in the offspring. The exception is the protective effect of high doses of FA regarding orofacial clefts in two specific predisposed breeds of dogs.\textsuperscript{28}

**Tumours, behavioural changes, metabolic syndrome and seizure**

Regarding mammary tumours, trials describing opposite outcomes were found: exposure to high levels of FA (5 mg/kg diet) during pregnancy and lactation may increase the risk of mammary tumours in rat offspring\textsuperscript{29} and the same dose of FA supplementation is suggested to lower the risk of this same outcome.\textsuperscript{30} Although the doses and the experimental models used were the same, the first paper investigates the effect of FA supplementation on chemically-induced mammary tumours, while the second paper explores the effect of this supplementation on spontaneous mammary tumours. It is likely that a high maternal FA environment may be protective against the development of spontaneous preneoplastic mammary lesions,\textsuperscript{30} but, on the other hand, it may increase the susceptibility to chemically-induced breast carcinogenesis in the offspring.

In the case of medulloblastoma, the only trial concluded that low maternal periconceptional FA levels, when compared to the recommended levels, may decrease the incidence of these tumours in mice genetically predisposed to tumour development.\textsuperscript{31}

Still regarding cancer, Sie et al.\textsuperscript{32} suggest that maternal, but not post-weaning, supplementation with FA in a dose equivalent to the average total folate intake in North America after fortification policy implementation is protective against the development of colorectal cancer in rat offspring. They also suggest that this protective effect may result from an increase in global DNA methylation and a decrease in epithelial proliferation in the colorectum.

In what concerns metabolic syndrome, one study showed that high FA supplementation during pregnancy may have an adverse effect by exacerbating the detrimental effect of high fat diet on glucose intolerance and insulin resistance in male offspring.\textsuperscript{33}

In addition, it was suggested that unregulated high FA supplementation during pregnancy may lead to alterations in brain development resulting in changes in behaviour.\textsuperscript{34} And finally, 4 mg FA/day before and during gestation, seems to decrease by 42% the offspring’s seizure threshold.\textsuperscript{35}

**Human studies: health outcomes of the offspring**

Almost 2/3 (n = 74) of the included papers were focused on studying, in humans, the role of maternal dietary FA supplementation over the foetal and child’s health (Table 2).

Of the 74 papers, a recurrent outcome studied was embryo’s defects (n = 29), including: NTDs (n = 8), orofacial clefts (n = 7), heart defects (n = 5), bladder exstrophy/epispadias/hypospadias (n = 4) and other congenital abnormalities (n = 5).

Seven of the included papers focused on offspring’s tumours (brain tumours (n = 4) and leukaemia (n = 3)) and 4 of the included papers concluded about offspring’s asthma (n = 4), low tract infections (n = 2) or allergy/atopy (n = 4).

Also we can observe a major concern regarding infant foetal growth (n = 5), behaviour problems (n = 3) or autistic disorder (n = 2) and neurodevelopment/memory (n = 5). Other studied outcomes were offspring’s bone turnover/development (n = 2), DNA methylation (n = 3), semen characteristics (n = 1), body composition (n = 1), blood pressure (n = 1), metabolic syndrome (n = 1) and, at last, schizophrenia/psychotic symptoms (n = 1) and psychomotor development (n = 2).

FA – folic acid; 5-MTHF – 5-methyltetrahydrofolate; DHA – docosahexaenoic acid; NTDs – neural tube defects.

NTDs

Focusing our attention on NTDs, of the 8 papers, 6 suggest a protective effect of FA supplementation in the occurrence of such defects. Importantly these papers highlight the importance of the pre/periconceptional period.36-41 The remaining 2 articles conclude that, in a background of FA fortification, FA supplementation or its absence are not associated with the risk of NTDs.42,43 Notably, all the included studies focusing on NTDs were of the case–control type, with a large sample size, except one48 that included about one hundred participants among cases and controls. So, it seems reasonable that pre/periconceptional FA supplementation indeed plays a role in the prevention of NTDs.

Oral clefts

Looking towards FA supplementation and the occurrence of orofacial clefts, 4 papers highlighted a possible protective effect in early pregnancy.44-47 Other two publications discussed the possible protective effects of FA supplementation on this congenital defect but they did not show any association regardless the use of 0.4 mg or 4 mg/day of FA by mothers.48,49 Just one publication reported an increased risk of orofacial clefts when there was a consistent supplement use during the aetiological relevant period (weeks 0–12 post conception)20 and these results led their authors to decisively emphasize the idea that it would be advisable to restrict FA supplementation to the period recommended for NTDs until more information is available. Indeed, when the exposure to FA is restricted to “early pregnancy” period (first week/first trimester post conception), among five studies only one demonstrates an adverse effect, while four of them consistently showed a beneficial protective effect against orofacial clefts. Importantly no extra effects were reported on higher doses of supplemented FA (4 mg/day comparing to 0.4 mg/day).

Heart defects

Offspring’s heart defects were covered by five of the included papers, four of them reporting a reduction in the risk of heart defects among offspring of mothers supplemented with FA.51-54 regardless of the time and dose of exposure. In fact, the authors observed beneficial effects even for high dose of FA51,52 (5 and 6 mg/day) and others show the same effect with only 0.4 mg FA/day.54 In addition, one of the studies revealed that FA supplementation can be related to a reduced risk of congenital heart defects, the preconceptional period as a critical window for this protective effect.55

Other general congenital defects

Five studies reported the effects of maternal FA supplementation on bladder defects (epispadias, hypospadias, bladder extrophy), most of them concluding on the possible protective effect of FA supplementation in the periconceptional period56,57 or suggesting that this supplementation could potentially alleviate phenotypic severity of these defects.58,59 Other findings regarding congenital defects also revealed a protective effect of FA supplementation on the risk of microtia60 or gastrochisis,61 while the lack of FA supplementation seems to be associated with observed meiosis II nondisjunction errors in older mothers.62 Another study support the protective effect of FA against several congenital defects.63 In contrast to the beneficial outcomes, it seems that higher doses of FA, although with low statistic correlation, might have an adverse effect by causing more plagioccephaly cases.64 An Australian case–control study reported no evidence of folate (either FA supplements or dietary folate intake) as an important factor in the prevention of birth defects other than NTDs.65 With the obtained results, we cannot fundament a hard statement on timings and doses but, in the case of bladder defects, a protective effect of FA supplementation was unanimously reported, when started before conception. In the other cases, no statements can be drawn because there are few cases of each reported outcome.

Offspring’s tumours

Several papers (n = 7) were focused on the relationship between FA supplementation in pregnancy and the risk of offspring’s tumours. Regarding brain/nervous system tumours, all the selected studies indicate a possible protective role of supplementation with FA during pregnancy in childhood brain tumours.66-68 No critical temporal windows of the maximum benefit of this supplementation are reported but, in three of the papers, preconceptional period and the first trimester of pregnancy seem to be determinant.

On the other hand, findings regarding the risk of offspring’s leukaemia are less expressive, as FA supplementation is reported as having an inverse borderline association if supplementation is started three months before conception,70 or no association with the risk of childhood acute lymphoblastic leukaemia.71,72

Respiratory and allergic outcomes

The interest on this area of knowledge is covered by the publications (n = 10) regarding childhood asthma, low respiratory infections or atopy/allergy. One study suggests that offspring of mothers that were supplemented with FA during the first trimester of pregnancy, had higher relative odds of being diagnosed with bronchiolitis compared with the group of no supplementation73 and other study reports that FA supplementation in pregnancy is associated with slightly increased risk of wheeze and lower respiratory tract infections up to 18 months of age, consistent with epigenetic mechanisms.74 Other study suggests a higher general risk of asthma in the offspring of supplemented mothers and, furthermore, if this supplementation is performed late in pregnancy,

</table>

FA – folic acid; 5-MTHF – 5-methyltetrahydrofolate.
there might be a significantly increased risk of asthma.\textsuperscript{11} Higher risks were documented with higher doses of FA supplementation (above 72 mg during the whole pregnancy, corresponding to 180 days of supplementation with 0.4 mg/day).\textsuperscript{75} Only one study did not show any relation with FA supplementation and higher risk of asthma at the age of six years.\textsuperscript{76}

Focusing on allergic outcomes, it is suggested that high maternal plasma folate and serum vitamin B-12 concentrations can be associated with the development of atopic dermatitis, but not with wheezing and shortness of breath in childhood.\textsuperscript{77} A dose-dependent effect was reported in the third trimester: infants exposed to ≥0.5 mg FA/day were more likely to develop eczema than those taking <0.2 mg FA/day.\textsuperscript{78} In contrast, one of the publications found no association between FA supplementation during pregnancy and atopic diseases in the offspring.\textsuperscript{79} Lastly, it seems that specific risk of childhood peanut allergy is not modified by maternal FA supplementation.\textsuperscript{80}

Another study also did not find association between prenatal FA supplementation and adverse respiratory or allergic outcomes in children of 1–8 years of age.\textsuperscript{81}

So, of the 10 articles that cover respiratory and allergic outcomes of the offspring, seven report an adverse effect of FA supplementation, three of them highlighting the adverse effect of supplementation in late pregnancy. However adverse effects are also seen for periconceptional period exposure or for reported high FA intake. Of the 10 articles, only three report no association between FA supplementation during pregnancy or the periconceptional period over these same outcomes. Thus, it seems plausible that FA supplementation, particularly in late pregnancy, will increase the risk of respiratory or allergic outcomes in the offspring.

**Behaviour problems, neurodevelopment and psychomotor disorders**

These are also some of the most addressed outcomes in what concerns FA supplementation (n = 10). The included evidence suggests that FA supplements in pregnancy can be positively associated with children’s neurodevelopment at the age of four years,\textsuperscript{82} being corroborated by other studies showing a possible effect of FA supplementation on enhanced vocabulary development, communication skills and verbal comprehension at 18 months of age (but not doses ≥5 mg/day)\textsuperscript{83} as well as a reduced risk of severe language delay in children at the age of three.\textsuperscript{84} Nonetheless, evidence also demonstrates no association with child memory at seven years old\textsuperscript{85} and no significant effect of supplementation on the cognitive function of children.\textsuperscript{86} Contradictory findings about psychomotor development were established as some evidence points towards a higher risk of delay within the use of FA supplements, at doses above 5 mg/day,\textsuperscript{87} while other authors suggest that prenatal FA supplementation may improve development at the age of three, reporting also a significant poorer performance in the personal-social domain.\textsuperscript{88} Facing these results, no conclusion can be extrapolated as data seem to be in discordance. In terms of behaviour problems, higher risk of hyperactivity and inattention has been attributed to an inadequate use of FA during the first trimester of pregnancy,\textsuperscript{17} also estimating that omission errors seem to be lower in children whose mothers took dietary supplementation with FA during pregnancy.\textsuperscript{88} Additionally, although in a small association and with possible confounding, lower folate status in early pregnancy might impair foetal brain development and induce hyperactivity and inattention problems in childhood.\textsuperscript{89} Though, still in what concerns behaviour problems, it seems that there is no association between lower folate status during pregnancy and the appearance of such kind of outcomes.

Autistic disorders are also one of the possible outcomes for the offspring and it seems that a lower intake (less than 0.6 mg/day) increases the risk of having children with autism spectrum disorders, and this risk was strongest for mothers and children with inefficient folate metabolism (MTHFR 677C>T variant genotypes).\textsuperscript{90} Also, a more recent cohort study suggests that prenatal FA supplements around the time of conception (dose of 0.4 mg/day) seem to be positively associated with lower risk of this type of disorders.\textsuperscript{91}

**Foetal growth and other outcomes**

A high FA dose (4 mg/day) in the periconception seems not to compromise foetal growth, when compared with a recommended dose of 0.4 mg/day.\textsuperscript{48} Other study reported that the periconceptional use of FA supplementation greater than 1 mg/day can be associated with decreased birth weight.\textsuperscript{92} However, periconceptional FA supplementation in recommended doses (0.4–0.5 mg/day) can be associated with increased foetal growth, and higher placental weight, resulting in higher birth weight and decreased risk of low birth weight or small for gestational age (SGA).\textsuperscript{93} On the other hand, low dietary folate intake or low plasma folate concentrations during the second trimester of pregnancy seem not to affect birth size.\textsuperscript{94} In addition, a trial comparing maternal multi-micronutrient with iron-FA or FA only did not support a greater advantage of the first on child growth during the first 30 months.\textsuperscript{95} Notwithstanding, foetal growth restriction commonly observed in situations of short interpregnancy intervals, was more frequent when folate depletion occurred.\textsuperscript{96} Once again, inconsistency regarding the effects of FA supplementation in the periconceptional period is observed. Regarding the impact of a low folate status, it seems relevant for foetal growth impairment only when it results from short interpregnancy intervals.

Other observed effects of FA supplementation during pregnancy were bone turnover/development with the suggestion that daily FA supplementation of 1 mg during pregnancy could have a positive impact in bone turnover both in mothers and newborns, thus concluding that both pregnant mothers and their foetuses could benefit, in this particular parameter, from FA supplementation during the whole pregnancy.\textsuperscript{97}

Another older publication refers to an association between maternal folate intake (cohort study with mean FA supplementation of 0.257 mg/day) and bone development in childhood, observed as volumetric bone mineral density of the spine regardless of height and weight.\textsuperscript{98} Both studies lead to the expectation that FA supplementation may be beneficial in terms of bone health later in life.

In addition, FA intake during foetal development was causally related to subtle and persistent DNA methylation (IGF2/H19) in the offspring of FA supplemented mothers and such results may lead to a further understanding of the foetal origin of adult diseases,\textsuperscript{99} also corroborated by other authors.\textsuperscript{100,101} Other observed isolated outcomes were, for instance, semen characteristics of the offspring, with no differences found between those whose mothers did not take FA or with unknown supplementation, in relation to the supplemented ones.\textsuperscript{102} No evidence was found to support the hypothesis that maternal dietary folate intake and intra-uterine exposure to folate is related to body composition of the offspring at the age of nine years,\textsuperscript{103} as well as no association on offspring’s blood pressure was documented.\textsuperscript{104} An experimental study in Nepal revealed that FA supplementation during pregnancy appeared to have the greatest beneficial effect on both offspring’s kidney function and lower risk of metabolic syndrome among the offspring.\textsuperscript{105} Finally, there was no support on the idea that maternal FA intake during pregnancy contributes to common aetiological
pathways that are shared between schizophrenia and non-clinic psychotic symptoms in adolescents.106

Human studies: health outcomes of pregnancy or the mother

Looking into the casuistry of the outcomes of FA supplementation in pregnancy or maternal health, 18 papers were identified, roughly divided in pregnancy complications or delivery outcomes \( (n = 13) \) (Table 3). Seven of these papers cover placental abruption and preeclampsia, six are associated to preterm birth or gestational age, three focus on abortion and other two on haematological status/homocysteinaemia \( (n = 2) \).

Pregnancy complications, abortion and delivery outcomes

No concordance was found on the protective effect of FA supplementation regarding preeclampsia and gestational hypertension (GHT). Some studies found that this intervention may help to prevent preeclampsia and associated SGA107,108 as well as placental abruption.109 Meanwhile, other research found that the dose of 0.4 mg/day FA alone in the early pregnancy cannot prevent GHT and preeclampsia.110

Regarding preterm delivery we found four studies where a protective effect of preconceptional and/or prenatal FA supplementation has a protective effect109,111–113 and another study114 that reported no protective effects or even an increase of the risk if the supplementation starting more than 8 gestational weeks. Shaw et al.115 concluded in their study that the role of FA on preterm delivery is no clear.

Concerning abortion, results were totally different among the publications, as some defend that high dose FA (4 mg/day versus 0.4 mg/day) does not increase miscarriage risk116 while others conclude that FA supplementation was protective on missed abortion.117,118 So, it is difficult to conclude about the real outcomes of FA supplementation, when regarding these areas, even considering studies involving large sample sizes.

Haematological status of pregnant women

Other studies analyzed haematological status of pregnant women and reported reduced risk of anaemia in the first trimester for 0.4 mg/day FA supplementation, but not latter in pregnancy119 and that higher doses of FA are not associated with the lowering of homocysteine concentration.120 With two totally different outcomes in terms of haematological status, no conclusions can be drawn.

Discussion

A period of ten years retrieve more than 1000 papers dedicated to the theme of FA supplementation in the context of pregnancy which were conducted all over the world. After thorough filtration for inclusion/exclusion criteria even the remaining papers corresponded to widespread contributions from the different continents reflecting the growing and widespread scientific interest in this particular area of knowledge.

Although reviews were excluded from the study, they indeed represented a huge part of the total papers retrieved in the search \( (n = 227 \) of the 1182) and this also shows the growing interest and need of systematization of the huge amount of gathered information on the use of FA supplements during pregnancy.

Animal trials focused essentially on gene expression and methylation, and they found evidence to support that gene expression and methylation suffer the influence of high doses and longer periods of FA supplementation.22,23,34

In what concerns human studies, from this review we can extract several general findings: first, we found studies covering associations of FA supplementation with a wide range of health outcomes over the offspring or over the mother/pregnancy. Second, the observed associations are beneficial effects in the majority of the studies, but there are also many studies reporting either no effects (high) FA supplementation during pregnancy or, importantly, adverse health effects. In addition, regarding the increasing concerns about the potential health effects of excessive exposure to FA during in utero development, there are just a small number of studies with the ability to conclude about this issue. Indeed, more human studies, and specifically human trials, are needed to ascertain about the safety of exposure to excessive amounts of FA during pregnancy. However we should be aware of the ethical issues that arise in this kind of studies. Throughout the review, we found few human trials and, as they focused on the effect of FA associated with other vitamins and/or nutrients, almost all of them were excluded as it was not possible to attribute the observed effects to FA supplementation per se.

Although, numerous outcomes associated with exposure to FA have been studied and some findings appear to be clear and consistent throughout the literature, others are not. There are several factors that may contribute to this difficulty in establishing clear associations: firstly, the difficulty in establishing the timing of supplementation with accuracy (more feasible in cohort studies, but very difficult in case–control studies, widely used for the study of rare outcomes, such as congenital defects or tumours), the dosage supplemented, as well as the combination of these two pieces of information – the timing and dosage – analyzing the data. Moreover, it cannot be forgotten that the studied outcomes are not entirely justified by FA supplementation but that in addition many of the determinants of taking folic acid – e.g. socio-economic factors, planning and vigilance of pregnancy – may also determine the studied outcomes – e.g. preterm delivery, size at birth. Also, many of the included publications describe studies that were performed in countries where fortification is mandatory, that may be a confounder weakening the magnitude of the association between the supplementation and outcomes.

In general lines, the main outcomes of the publications included in this review are in offspring’s health, namely in relation to congenital defects, allergy/respiratory problems, cancer and psychomotor and neurodevelopment outcomes. As a great variety of studies were focused on diverse outcomes, and established the role of FA supplementation throughout different dosages and timings of exposure, and even in different populations (e.g. with mandatory fortification), it is hard to conclude about the real implications of such intervention. Regarding NTDs, the protective role of FA supplementation seems to be unquestionable. It seems consensual that a supplementation of 0.4 mg FA in the periconceptional period allows the protection against NTDs, with no associated harmful effects. The harmful outcomes, including epigenetic changes, that have been subject of much attention, are associated with the supplementation that occurs at higher doses and/or extended throughout pregnancy116,22,23,101 and not just in the periconceptional period.

Regarding animal studies, many of them use the recommended dose of FA for pregnancy in the rat (2 mg/kg of diet) but also higher doses of FA (corresponding up to as much as 20 times the recommended dosage, with 8 mg/kg of diet as the most commonly used). This allows us to observe clearly the health impact of excessive doses of FA, much more than in the human observational studies. Although they have obvious limitations in extrapolating the results to human reality, these studies are very important because they allow freedom for interventions that may give clues to the effects which cannot be obtained in human trials.
It is somehow a priority to inform all health professionals who work with pregnant women that despite FA is a water soluble vitamin which is therefore easily excreted whenever it is in excess, in cases of FA supplementation (with the synthetic form) this excess may not be as harmless as it is thought to be and the real impact in later life is still not totally known. So, it is important to raise the awareness on the importance of respecting the right doses at the appropriate intervals, clarifying its safety.

As referred above, there is an urgent need to establish the critical dosages, and also importantly the critical timings to achieve the best outcome, avoiding possible harmful endpoints. Also, we find that it would be interesting to know more about what the professionals that daily work with pregnant women know about this issue, which will represent perhaps the most important key of intervention. We suggest that research should be performed in order to understand exactly how they prescribe on the field, their knowledge, their doubts and also, possible confounding factors that may interfere with the prescription of this type of supplementation, namely if the pregnant women’s opinion/knowledge is important or not in their decision.

Limitations of this review should be considered. First of all, we only included a period of ten years, allowing the potential omission of the information published mainly before the time period considered. However, considering the huge amount of papers published in this period, we believe that the current state of the art is herein suitably represented. We are also aware that our inclusion/exclusion criteria may influence our findings. But even considering only healthy pregnancies, without any adverse exposure, authors obtained contradictory results. So, the inclusion of such additional studies would certainly tangle the revision and possibly impair the extraction of clear conclusions. Another point that may weaken this review is the fact that not all the material obtained was, in fact, read by all of the three authors. Although this may lead to possible gaps and confounders, it was the best methodological strategy that enabled the achievement of our objectives. Importantly, the meetings, and the discussion and establishment of inclusion/exclusion criteria, contributed to the homogenization of the global work. Lastly, we found it difficult to discuss/conclude on the real and critical temporal windows of FA supplementation, either in terms of timings or doses. This task was hard because, for the same kind of outcome we obtained different type of studies, sample sizes and interventions. In view of this, we consider that any conclusions extracted may represent very useful information.

We also find many strengths in our work. First, it is a summary of the evidence of the different works all around the world, regarding FA supplementation and its possible beneficial and harmful outcomes, not only in terms of pregnancy itself, but also in mothers and offspring’s future health. So, this review may be an important tool for the identification of questions for future research, as well as in terms of health practices, as it intends to highlight the global knowledge in the last years. Also, as we only included outcomes directly related to isolated FA supplementation, focusing on the central matter, the gathered data may be a start point for future works, namely regarding the definition of critical temporal windows and safety doses of exposure, an emergent contributor for Public Health policies.

Conclusions

There is an unequivocal growing interest around FA supplementation in pregnancy, reflected by the number and sort of studies that we found when performing this review, and also the diversity of specific outcomes they focused.

The majority of the publications reported FA supplementation effects on the offspring’s health, with emphasis in areas such as NTDs, allergy/respiratory problems, cancer and behaviour problems. In terms of each general outcome, we frequently observed some heterogeneity, except for the case of NTDs. In spite of the possible protective effect of the FA supplementation in many outcomes (e.g. NTDs, heart defects, other general congenital malformations, autistic disorders, birth size, bone turnover, abortion, as others), we also denote a rising concern on the excessive effects of supplementation, whether in terms of doses or times of exposure.

Animal trials, even though representing a small part of this review and with obvious difficulties in extrapolation for human reality, also contribute towards the understanding of the molecular and particularly epigenetic pathways that may be the base of offspring’s (and also maternal) persistent modifications liable to cause disease in the future generations.

In terms of real and perceived critical temporal windows of supplementation, we can see that the protective effect of FA supplementation against NTDs is very prevalent in the periconceptional period, while the adverse effect on allergy/respiratory problems is much associated with exposure in later periods of pregnancy, mainly if this exposure lasts the whole pregnancy period. Regarding the effective dose, it seems that a daily dose of 0.4 mg in the periconceptional period causes no damage.

Critical doses and time of exposure should be the focus of future research in this area.

Conflicts of interest

The authors declare no conflicts of interest.
