Rostrum
The path toward an HIV-1 vaccine
Fernando Garces
Therapeutic Discovery, Amgen, Inc., CA, United States

ABSTRACT
HIV is responsible for millions of deaths around the world and in the absence of available treatment capable of a cure, only the vaccine can offer protection against this virus. However, and after three decades of research, such a vaccine remains elusive. Here, I attempt to explain the major challenges on the development of an anti-HIV immunogen, and how the three-dimensional pictures of antibodies interacting with this virus can guide us to the design of a successful vaccine.

these two. Naturally, for its immunogenic properties, the structure of the pre-fusion state is of major importance for the scientists because neutralizing Abs recognize this Env state. However, a clear picture of the three-dimensional structure of HIV-1 Env protein remained elusive for decades. In the past 5 years we have achieved notable breakthroughs in the field of HIV structural biology leading to the determination of several high-resolution crystal and cryo-EM (electron microscopy) structures of the HIV pre-fusion Env. The laboratory of Professor Ian Wilson, at the Scripps Research Institute, spearheaded most of the effort that lead to the successful determination of the first crystal structure for an HIV-1 Env protein. Wilson and colleagues engineered a soluble HIV-1 trimer platform where the conformation of this extremely flexible and unstable protein is locked in the pre-fusion state, enhancing the conditions to grow Env protein crystals. The outcome of this outstanding research is reported in top scientific journals and unveils the atomic details of this long-sought-after protein structure, offering a plausible explanation as to why previous attempts to produce a vaccine may have failed.

New path to vaccine: structure-guided immunogen design

These high-resolution Env structures not only shed light on the molecular details of the HIV-1 fusion mechanism but also, and perhaps most importantly, provided us with the clear mapping of the neutralizing antibody epitopes (regions of antibody recognition) of those broadly neutralizing antibodies (bNAbs) isolated from HIV-1 infected patients. Such knowledge is of paramount importance since the immunogens to be used in a potential vaccine regimen must contain all the components required for antibody recognition and binding. Notably, Wilson and colleagues also discovered that the same epitope recognized by a mature anti-HIV-1 antibody is not necessarily the same epitope that a precursor antibody will bind to. Indeed, work published in Cell by Garces, Wilson and colleagues, identified structures within the epitope (i.e. glycans) that partially block the binding of germline Abs, which are the precursors to the bNAbs isolated from infected HIV-1 humans. These observations had a profound impact in the understanding of the many hurdles involved in triggering the right B cells to initiate antibody affinity maturation leading to a bNAb. These observations also led to the design of a sequential set of immunogens to be administrated in a controlled fashion in order to teach the immune system, step by step, how to generate the desired bNAb.

Proof of concept

Although the vast structural information provided us with valuable knowledge of the intimate relationship between the HIV-1 virus and the human immune system, the direct test of a vaccine in humans is beyond consideration. Fortunately, the availability of new animal models (humanized mice) allowed scientists to prove that immunization strategies, using a series of modified Env proteins, can lead to the development of bNAbs. These mice have cells (B cells) that produce antibodies known to be the precursors of broadly neutralizing antibodies against HIV-1. The series of Env proteins used to immunize these mice, guided the maturation of the precursor antibodies to become antibodies that could efficiently neutralize HIV-1 viruses.

Is the HIV-1 vaccine within reach?

This billion-dollar question does not have a simple answer. The structure-guided rationale presented above shows promising results in animal models, demonstrating that this approach is indeed capable of eliciting Abs similar to those bNAbs isolated from HIV-1 infected individuals. Similarly, neutralizing antibodies isolated from Ebola patients were used to successfully treat many patients from the latest Ebola outbreak responsible for 11 thousand deaths in West Africa. So does all of this scientific progress indicate that we will, in time, produce a successful vaccine against the HIV-1 virus? Let’s go step by step. The HIV-1 virus exhibits an extraordinary mutational rate, higher than the Ebola, Hepatitis-C and Influenza viruses. To better illustrate this difference we could say that the genetic diversity within a single HIV-1 individual is equivalent to the diversity for the Influenza virus globally, and still the flu vaccine does not always show 100% efficacy. Because the HIV infected individual can live for many years as a virus carrier, it would be important to develop an HIV vaccine that is easily administered and available to everyone in the world to maximize protection coverage, since just one infected individual can spread the disease over such a long period of time. Although we do not have an efficacious vaccine today, the research on the HIV vaccine is also helping to overcome some limitations in our understanding of the immune system in humans. How B cells first recognize the antigens and the role of germinal centers is still largely unknown but may be of tremendous importance to develop a vaccine capable of developing bNAbs. It is also possible that in the pursuit of an HIV-1 vaccine, we may well advance our understanding of the Immune system to a point where other vaccines may be developed. An example of this, is the structure-based vaccine recently developed to prevent Respiratory Syncytial Virus (RSV) infection in infants, where high resolution envelope glycoprotein crystal structures were used to generate an immunogen that improved the current RSV vaccine.
